

Squaring both sides, and using the definition for $v_s = L/\tau = 2\pi f\tau L$, we obtain after some cancellation

$$2W/\epsilon AL = E^2. \quad (7)$$

Recognizing AL as the volume of the specimen, we have finally

$$U = \frac{1}{2}\epsilon E^2, \quad (8)$$

where U is the energy density within the material.

We see, therefore, that Eq. (1) is simply a restatement of the energy-density conservation law for electrostatic fields, that is, the maximum electrostatic energy density which can be sustained by a material without breakdown is given by (8) in terms of the material constant ϵ and the dielectric breakdown field E .

The fact that this, perhaps, is an obvious result should not detract from its implications, since Eq. (1) which is a consequence of it (as are the more familiar gain bandwidth relations) is quite useful in choosing among alternatives for investigation.

⁶ The derivation, which among other factors involves the computation of the maximum current that can be sustained in a transistor, is open to some question since it assumes that base widening is the controlling factor. In that evaluation, the collector depletion-layer transit time is set equal to the average transit time from emitter to collector, which along with some other assumptions is far from the truth. However, it gives the correct form of the dependence if not the absolute value.

Experimental Verification of Pressure Enhancement by Encapsulation*

JAMES A. CORLL

Sandia Laboratory, Albuquerque, New Mexico

(Received 11 November 1966)

In this note we report experimental results which verify the pressure enhancement by encapsulation previously suggested¹ on theoretical grounds. The experiments consisted of comparing the occurrence of a pressure-induced change of state in encapsulated and unencapsulated samples. The sample material chosen for this study was a ferroelectric ceramic,² which undergoes a pressure-induced transition from the ferroelectric state to the antiferroelectric state at approximately 40 000 psi.

Two spherical samples were ground from a single billet of the ceramic and electroded to form capacitors. One of the samples was encapsulated in an epoxy³ sphere and the samples mounted in a hydrostatic pressure chamber for simultaneous testing. The samples were then poled in the ferroelectric state by the application of 1000-V dc, which placed a bound charge of approximately $1 \mu\text{C}$ on each sample. The fluid pressure in the chamber was then raised at about 800 psi/sec and the charge released by the pressure-induced transitions of the samples recorded on a dual-pen autograph. The horizontal axis of the autograph was driven by a transducer monitoring the pressure in the chamber.

Figure 1 is a reproduction of the data recorded by the autograph during a typical experiment and displays a pressure enhancement of approximately 15% due to the encapsulation. During the experiments, the zero points of the curves were arbitrarily displaced vertically for clarity and slightly displaced horizontally by the two-pen arrangement of the autograph. To verify that the effect observed was due to the encapsulation, several variations of this experiment were performed (including removing the epoxy from the encapsulated sample and encap-

sulating the other sample). In all cases, the encapsulated sample discharged at lower applied pressures than the unencapsulated sample.

Although a numerical comparison between theory and experiment is limited by the lack of accurate data concerning the elastic parameters of the materials, calculations with estimated values⁴ predict the pressure enhancement should be between 10 and 20%. The Poisson's ratio of the encapsulating material is the controlling factor in the calculation of the expected enhancement [Ref. 1, Eq. (7)], and greater enhancement would have been encountered in these experiments if an encapsulating material with a low Poisson's ratio had been used. The fact that a pressure enhancement of approximately 15% was observed even with a high Poisson's ratio encapsulating material such as epoxy, emphasizes the potential importance of the effect to high-pressure experiments. Encapsulation effects are an inherent part of all experiments at very high pressures or low temperatures in which the pressure medium is a solid. Consideration of these effects should be included during the interpretation of the pressure-induced phenomena, as well as for an accurate pressure calibration in such experiments.

The author gratefully acknowledges the technical assistance of B. E. Hammons throughout these experiments.

² $\text{Pb}_{0.99}\text{Nb}_{0.02}(\text{Zr}_{0.80}\text{Sn}_{0.20})_{0.99}\text{Ti}_{0.01}\text{O}_3$.

³ The epoxy used was a 100/20 mixture of Hysol 6020 resin and AX hardener, which cures at room temperature overnight.

⁴ Using the notation of Ref. 1: $N=1$; $\xi=0.24$; $\eta\approx 0.12$; and $0.40 < \nu < 0.46$. These values were estimated from rough measurements on the epoxy and assuming the compressibility of the ceramic to be 6.0×10^{-4} kbar.

Effect of Aluminum Doping on the Fluorescent Emission of CdS*

JICK H. YEE AND GEORGE A. CONDAS

Lawrence Radiation Laboratory, University of California, Livermore, California

(Received 5 December 1966; in final form 23 January 1967)

This communication deals with an examination of the low-temperature fluorescence of single crystals of CdS that were doped with small amounts of aluminum. Phosphors made by relatively heavy doping of CdS with aluminum, as well as other group III metals, have been investigated in the past.¹ However, doping
