

cracks running perpendicular to the direction of compression. The compressibility of the transducers seems to be independent of the pressure between the cracking. The data, but pulse-echo method. If the measurements had been made with the quartz transducer, the accompanying this effect would have back reflected the dependence of the specimen length was not at this slight cold unimportant.

and two transverse waves with pressure, were used in the pulse-echo method. The data for this work is in the 10-Mc band preamplifier. The pattern on the face of the oscilloscope shows the details of each specimen structure of each run. The sweep rate is 10 Mc/μsec. The A/R oscilloscope has an external resistance measurement of 0.001 ohms possible. In practice, the changes of transit time are the change in time of the 10-Mc/sec time marker, as shown down several times in the unrectified pulse-

echoes is less prone to errors arising from change of pulse-echo shape with pressure than is that using gear which displays the rectified pulse-echoes. A typical data plot is given in Fig. 1 showing the difference between time of arrival of one of the maxima of echo No. 7 and the  $C_{44}$  wave in a 1.9-cm long copper crystal and a time-marker, as a function of pressure gauge coil resistance. The pressure range indicated is about 9800 bars. Data points were taken about 5 min after each pressure change in order that the system be near thermal equilibrium. Absence of hysteresis justifies the time interval chosen. Strictly speaking one is interested only in the initial slopes of these curves, but experimentally all the plots are linear over the pressure range used. The slope of this line can be determined by a least squares method and this slope, together with the measured zero pressure transit time, enables one to compute the quantity  $(nT_0)^{-1}dT_n/dR_g$ , where  $T_0$  is the zero pressure transit time,  $n$  is the number of the echo under observation,  $T_n$  is the observed time of arrival of the  $n$ th echo and  $R_g$  is the pressure gauge coil resistance. Since one can express the pressure gauge coil calibration as  $dP = KdR_g$ , and  $T_n(P) = nT(P)$ , the quantity  $k^{-1}(nT_0)^{-1}dT_n/dR_g$  represents the fractional change of transit time with pressure,  $(T_0)^{-1}dT/dP$ .

A sequence of observations made with increasing pressure or with decreasing pressure will be called a run. Sets of runs made with a given transducer cemented in place will be called an experiment. Each value of  $(T_0)^{-1}dT/dP$  which has been used is the result of at least two experiments each of which consisted of at least two runs. In the case of copper this procedure was followed for each of three crystals.

For crystals of nearly [110] orientation the equations relating transit times to elastic constants are given by

$$\begin{aligned} Y_2 &= B_s + 4\left(\frac{1}{3} - \Gamma\right)C' + 4\Gamma C, \\ Y_4 &= C + 2a_1(C' - C), \\ Y_5 &= C + 2a_2(C' - C), \end{aligned} \quad (1)$$

where

$$\begin{aligned} Y_2 &= \rho V_2^2 = 4\rho L^2/T_2^2, & Y_4 &= \rho V_4^2 = 4\rho L^2/T_4^2, \\ Y_5 &= \rho V_5^2 = 4\rho L^2/T_5^2, \end{aligned} \quad (2)$$

$T_2$  is the transit time for the longitudinal wave, and  $T_4$  and  $T_5$  refer to the slow and fast shear wave transit times, respectively.  $L$  is the length of the specimen between acoustic faces and  $\rho$  is the density of the material under study. The notation,  $C = C_{44}$ ,  $C' = (C_{11} - C_{12})/2$  and  $B_s = (C_{11} + 2C_{12})/3$ , has been used.  $\Gamma$  denotes the adiabatic bulk modulus. The quantities  $a_1$  and  $a_2$  are orientation functions<sup>14</sup> which are independent of pressure for cubic materials. For orientations near [110],  $a_1$  is about 0.5 and  $a_2$  is nearly zero. For exactly [110] orientation one could write:  $Y_4 = C'$ ,  $Y_5 = C$ . That is,  $C'$  is determined by  $Y_4$  only, and  $C$  is found from  $Y_5$  only. Taking the derivative with respect to pressure, of each equation relating the

$Y$ 's and the elastic constants, one obtains

$$\begin{aligned} \frac{dY_2}{dP} &= \frac{dB_s}{dP} + 4\left(\frac{1}{3} - \Gamma\right)\frac{dC'}{dP} + 4\Gamma\frac{dC}{dP}, \\ \frac{dY_4}{dP} &= \frac{dC}{dP} + 2a_1\left(\frac{dC'}{dP} - \frac{dC}{dP}\right), \\ \frac{dY_5}{dP} &= \frac{dC}{dP} + 2a_2\left(\frac{dC'}{dP} - \frac{dC}{dP}\right). \end{aligned} \quad (3)$$

Taking the pressure derivative of the logarithm of any one of the equations relating the  $Y$ 's to the transit times, one obtains the relation

$$\frac{1}{Y} \frac{dY}{dP} = \frac{1}{\rho} \frac{d\rho}{dP} + \frac{2}{L} \frac{dL}{dP} - \frac{2}{T} \frac{dT}{dP}. \quad (4)$$

The first two terms on the right-hand side of the equation sum to  $(3B_T)^{-1}$ , where  $B_T$  is the isothermal bulk modulus, and the third term is the result of the measurements on changes of transit time with pressure, that is,

$$\frac{1}{Y} \frac{dY}{dP} = \frac{1}{3B_T} - \frac{2}{T} \frac{dT}{dP}, \quad (5)$$

with all quantities to be evaluated at zero pressure. Given the zero pressure values of all the  $Y$ 's and data on pressure variation of the transit times of the three waves, one can use the Eqs. (3) to compute the pressure derivatives of  $C$ ,  $C'$ , and  $B_s$  at zero pressure. These equations determine the pressure derivatives of  $C$  and  $C'$  quite directly in the case of a [110] orientation, but the pressure derivative of  $B_s$  is derived from a combination of all three measurements.

The acoustic surface of each crystal was etched and a back reflection Laue x-ray taken after all acoustic measurements had been made. Ten spots were indexed and a least squares determination of the orientation was made.

The entire procedure outlined above was carried out for one crystal of each of silver and gold, and for two copper crystals of different lengths but similar orientation. Two copper crystals were used in order to form an estimate of the importance of any end effects such as nonhydrostatic stresses on the end of the specimen caused by differential compressibility of the quartz transducer and the metal, and possible change with pressure of acoustic end effects. The end effects proved to be less than the random experimental variations for copper, so that we felt reasonably safe in making measurements on one crystal only of each of silver and gold. These crystals just referred to were all within  $2^\circ$  of the [110] orientation. In addition, measurements were made on the pressure variation of the longitudinal wave transit time using a third copper crystal, near the [100] orientation.

reference between time of arrival of a nearby time marker and the pulse-echo. The curves represent the data for the sake of clarity. The data are from experiment No. 1 for  $C_{44}$  wave in the pressure range covered.
