

where  $\Delta$  denotes the change through the phase transition. Let us apply this at the hypothetical case of a two-phase liquid triple point at  $125 \text{ kb}$  and  $2500^\circ\text{K}$ . We know that the volumes of the coexisting phases must be very similar at this pressure because of the agreement between the coexisting static-compression data and the coexisting Hugoniot data (Figure 6). If the difference in their volumes is zero, (22) shows that the coexisting liquid phase line is horizontal in Figure 8 (also shown by line 1 in Figure 9, which illustrates the relevant region of the phase diagram in more detail). If the difference in volumes is not zero, the slope of the phase line can be estimated as follows. The coexisting triple point below the triple point is mixed below the triple point. The coexisting liquid phase line is still fairly well deter-

$$(22) \quad dP/dT = \nabla S / \nabla V$$

The Plausibility of this hypothesis can be tested by using the Clausius-Clapeyron relation for the slope of a phase line:

An alternative interpretation of the data is suggested by re-examining Figure 8, in which the lower-pressure quartz-liquid-gas region of the phase diagram is also shown [Levin *et al.*, 1969; JANAF Tables, 1965]. The stishovite-Hugoniot boundary intersects the calculated phase line at about 2500°K, which is comparable to the melting temperature of quartz. Is it possible that the coesite is the quarium? I would promote the transition to stishovite.

As can be seen in Figure 8, the calculated phase line deviates considerably from the line separating the coesite and stishovite Hugoniot fields. The difference is about a factor of 2 in temperature at the coesite, and stishovite Hugoniot separation from the coesite would be surprising if this phase were coesite, since it would be expected that the high temperatures involved in this phase would promote the transition to stishovite.

native equations of state given in the previous sections. The uncertainty due to the approximations used for  $U$ ,  $S$ , and  $S'$  is difficult to estimate, but it should not be greater than a few per cent. Errors of 5% in  $U$ ,  $-U'$ , and  $S'$  would cause errors of about 1% and 3%, respectively, in the calculated transition pressure at 10,000°K.

The phase line resulting from these calculations is shown in Figure 8. The error bars represent variations due to the use of the altered equations and sensitive to the emulsion.

$$+ \Delta P = V_p^0. \quad (21)$$

$$+ VP - V^0 p^0 \quad (21)$$

$$\wedge^p (L, \Lambda) D \int_A = d^p \Lambda \int_d$$

The integral in (17) is more easily evaluated here by noting that

$$(20) \quad {}^0S\nabla T - {}^0H\nabla + ({}^0A - {}^0A) {}^0D =$$

$$(L^{'_s}{}^0 A)_s \mathcal{D} = (L^{'_s}{}^0 A)_s \mathcal{D}$$

(19) becomes  
When it is noted, finally, that  $\Delta U_0 \approx AH_0$ ,  
(19) can be replaced by their values at 298°K.

To evaluate this expression we need  $U$  and  $S$  as functions of  $T$  for both sisalovite and coesite. These functions are known accurately [Holm et al., 1967] only up to 350°K. However, the difference  $U(V_0, T) - U(W_0, T)$  and the analogous difference for  $S$  can be approximated as being constant above about 350°K for the following reasons. The specific heats  $C_V$  of sisalovite and coesite given by Holm et al. [1967] converge toward each other above about 150°K. Also, at 300°K,  $C_V$  differs from  $C_W$  by about 0.6% for sisalovite and by about 0.1% for coesite. Thus the  $C$ , will also converge at higher temperatures. Because  $U$  and  $S$  are integrals of  $C$ ,  $U - U_0$  will approach a constant value at higher temperatures, as will  $S$ . — Thus the differences in  $U$  and  $S$  in (19) can be corrected by their values at 300°K.

$$(19) \quad [(L_{\sigma}^{\alpha_0} A)_\sigma S - (L_{\sigma}^{\alpha_0} A)_s S] L =$$

$$(L_{\sigma}^{(0)} A)_{\sigma} \Omega = (L_s^{(0)} A)_s \Omega +$$

$$({}_s^0A - {}_s^0A)(L)^0D = (L^{{}^*} {}_s^0A) {}_sD - (L^{{}^*} {}_s^0A) {}_sD$$

Now from (16), using (18), we obtain

MESSAGE FROM THE PRESIDENT

$$98 \text{ kcal/mole} = 7.36 \times 10^6 \text{ ergs/g}$$

The awards of  $\Delta H^\circ$  and  $\Delta S^\circ$  can be found from the results of Holm *et al.* [1967]. At 298 K

$$(8J) \quad {}^0S \nabla {}^0L = {}^0H \nabla \equiv {}^0Q \nabla$$

Indeed similarly, (14) gives

stishovite volume difference is about  $0.09 \text{ cm}^3/\text{g}$ . The entropy difference is, then, from either the slope of the phase line ( $0.02 \text{ kb}/\text{°K}$ ) and (22) or the approximation made in the previous section, about  $2 \times 10^6 \text{ ergs/g}^\circ\text{K}$ . When the liquid-stishovite volume difference is assumed to be also about  $0.09 \text{ cm}^3/\text{g}$ , the slope of the liquid-stishovite phase line ( $0.06 \text{ kb}/\text{°K}$ ) and (22) give the liquid-stishovite entropy difference as about  $5 \times 10^6 \text{ ergs/g}^\circ\text{K}$ . When these results are combined, the liquid-coesite entropy difference is about  $3 \times 10^6 \text{ ergs/g}^\circ\text{K}$ . From Figure 6 we can estimate a reasonable maximum volume difference between the coesite and the liquid to be about  $0.01 \text{ cm}^3/\text{g}$ . Equation 22 then gives a slope of about  $0.3 \text{ kb}/\text{°K}$  (line 2 in Figure 9). Line 3, which has the same slope as the stishovite-liquid phase line, would imply that coesite has a volume similar to that of stishovite, which is clearly unreasonable.

Lines 1 and 2 both extrapolate to the range of melting temperatures of quartz. There is a difficulty, though, since a similar set of relationships would hold at the quartz-coesite-liquid triple point, and thus we would be led to predict a slope of the quartz-liquid phase line rather different from the one shown. However, we may observe that the liquid would have to vary continuously from a density of about  $2.2 \text{ g/cm}^3$  at zero pressure (the density of fused quartz) to about  $3.1 \text{ g/cm}^3$  at 100 kb. This variation would cause the phase lines to be concave downwards (Figure 9) in this range and

might allow these relationships to hold without contradiction.

The preceding discussion is intended as a plausibility argument. It must be considered a serious possibility that a coesitelike liquid phase was produced in the shock-wave experiments.

To return, finally, to the coesite-stishovite phase line below the hypothetical triple point, the calculated transition pressure at  $300^\circ\text{K}$  is 78 kb. This value is in reasonable agreement with that of 69 kb estimated by Akimoto and Syono [1969] from their experimental results. It may also be compared with their values of 85–95 kb calculated by using a rough estimate of the coesite compressibility.

The average slope of the phase line is about  $0.023 \text{ kb}/\text{°K}$ , which compares very well with the value of  $0.024 \text{ kb}/\text{°K}$  found by Akimoto and Syono [1969].

*Note added in proof.* An analysis by E. K. Graham (unpublished manuscript, 1972) of some of the stishovite Hugoniot data analyzed here yielded the values  $K_o = 3.35 \text{ Mb}$ ,  $K'_o = 5.5$ , and  $\gamma_o = 1.64$ . A high value of  $K'_o$  was also obtained by Ahrens *et al.* [1970] ( $K_o = 3.0$ ,  $K'_o = 6.9$ ,  $\gamma_o = 1.58$ ). Although some differences between these analyses and the present analysis are due to the different equations used, a critical difference is that cases 2 and 3 of the present analysis rely on the Hugoniot data of the more porous samples to constrain  $\gamma$ , whereas those in the other analyses rely on Weaver's [1971] coefficient of thermal expansion. The effect of these different approaches can be seen by comparing case 1 with cases 2 and 3 above. Case 1 also relies on Weaver's data. The preference for case 2 rests on the critical assumption that the Grüneisen parameter does not vary greatly with temperature at very high temperatures.

*Acknowledgments.* I am grateful to Dr. Tom Ahrens for suggestions concerning the calculation of phase equilibria and to Dr. H. Mizutani for providing data in advance of publication.
