pends on the electron scattering. From the Hall effect we determine the electron density n, and then the effective mass is determined from the value of the thermal emf  $\alpha_{\infty}$  in the saturation region.

The measurements were made at temperature gradients 3 - 6 deg/cm; the difference in the temperature drops on opposite faces of the sample did not exceed 2%. The termocouples were introduced in the high-pressure chamber without a break of the continuity. The pressures were produced at nitrogen temperatures by a method proposed by Itskevich [1]. The investigated samples measured 10 x 3 x 2 mm.

In the absence of degeneracy and at low value of the non-parabolicity parameter  $\gamma = kT/\epsilon_g$ , the thermal emf in the saturation region equals, accurate to terms  $\sim \gamma^2$ ,

$$\alpha_{\infty} = \frac{k}{e} \left( \frac{5}{2} + \frac{15}{2} b \gamma - \frac{45}{4} a \gamma^2 - \mu_0^* \right), \quad (2)$$

where  $\mu_0^* = -\ln \left[2(2\pi m_n kT)^{3/2}/nh^3\right]$ , and a and b are some simple functions of  $\epsilon_g$  and  $\Delta$  (see [2]).

Figure 1 shows a plot of  $\alpha_m$  against P for two samples of n-InSb with n  $\simeq 2.2 \times 10^{14}$ cm<sup>-3</sup>, and Fig. 2 shows a plot of n vs. P. The pressure dependence of the effective mass m, calculated in accordance with (2), is shown in Fig. 3 for samples with  $n \simeq 2.2 \times 10^{14}$  (\*) and  $n = 4.7 \times 10^{13} \text{ cm}^{-3} (+)$ . The same figure shows a theoretical plot of m<sub>n</sub>(P) calculated from (1) (dashed curve). In the calculations we assumed that  $\epsilon_{g}(96^{\circ}K) = 0.226 \text{ eV}, \Delta = 0.9$ eV, and  $\epsilon_{\rm p}$  = 23 eV. With increasing pressure, the disparity between the experimental and theoretical curves increases and appreciably exceeds the experimental errors. Two possible causes of this disparity have been considered: (i) change of matrix element P with pressure, (ii) change of perturbation of the mass m by the remote bands with changing pressure.

To reconcile the experimental and theoretical values of  $m_n$  it must be assumed that  $\mathbb{P}^2$  increases by 20% at P = 5 katm and by 35% at 16.5 katm. If we recognize that at 16.5 katm the lattice constant increases by  $\approx 1.5\%$ , then admittedly such large changes in  $\mathbb{P}^2$  are unlikely.
