## Computation of Some Physical Properties of Lubricating Oils at High Pressures

## I. Density

R. B. DOW AND C. E. FINK School of Chemistry and Physics, The Pennsylvania State College, State College, Pennsylvania (Received October 24, 1939)

From a survey of available data on the density of fluid lubricants as a function of pressure and temperature, the following empirical equation has been derived:

## $\rho = \rho_0 (1 + ap - bp^2)_{\iota}.$

 $\rho$  is the density at a given pressure (gage) p and temperature t;  $\rho_0$  is the corresponding density at atmospheric pressure. The constants a and b are evaluated over a temperature range extending from 20° to 220°F and the density equation is valid over a pressure range of 50,000 lb./in.<sup>2</sup>. While the equation was derived from data on mineral oils it has been found to hold equally well for animal, vegetable, and fish oils. The variation of density with pressure is independent of the nature of the oil.

when to compute the thermodynamic charcreatics of an oil at high pressure it is such that the specific volume or density be a sta function of temperature and pressure. mur, in problems of lubrication design it is messary to convert from the dynamic to immatic coefficient of viscosity, and vice and in order to do this at high pressures dynsities must be known over the range of ar involved. It is the purpose of this paper ment a practical means for calculating an over a pressure range up to 50,000 lb./in.<sup>2</sup> interatures between 20 and 220°F. These a d pressure and temperature are those only encountered in many problems of in the fields of engineering and d physics, and although data could be readily at higher pressures, provided the temperature was also raised so that the remain fluid, the investigation would mome one of academic interest rather than importance.

<sup>1</sup> to be defined at a person of the second second

Now and M. R. Fenske, Ind. and Eng. Chem. 27,

at 104°F and 167°F at pressures up to 50,000 lb./in.<sup>2</sup>, and then fractionated the oil into narrowboiling cuts and obtained data on ten of these cuts.

The striking result of all these investigations is the fact that, within the range of experimental error, all of the oils have the same compressibility. Thus the oils studied in Europe by Hyde, who used the moving piston type of apparatus to make his measurements, showed the same behavior in this respect as the oils studied in this country by Dow who used the sylphon apparatus. Furthermore, the work of Dow included extreme types of oils such as a typical Pennsylvania oil which is noted for its high paraffinicity and low temperature coefficient of viscosity, and a typical Gulf Coast oil which is characterized by the fact that it contains large amounts of naphthenic and aromatic types of molecules and has a relatively high temperature coefficient of viscosity. The work of Dow and Fenske, moreover, shows that the generality in regard to compressibility may be extended to narrow-boiling fractions which vary considerably in boiling point and molecular weight. This insensitivity of compressibility, within the range of experimental error, among the wide variety of oils studied is strikingly different from other properties that have been studied under pressure, as, for example, viscosity.4

From an experimental standpoint, therefore, <sup>4</sup> R. B. Dow, J. App. Phys. 8, 367 (1937).

OURNAL OF APPLIED PHYMAN

the available density data for oils at high pressure appear to be adequate for present needs. The fact that all of the oils studied show the same compressibility indicates the desirability of constructing standard density-pressure curves. The practical means adopted by the writers to express these curves in a form convenient for calculation of density at high pressure is an empirical equation that reproduces the standard curves that were drawn as averages of the experimental data. Interpolation and extrapolation were used, as explained later, to amplify and extend the range of usefulness of the equation.

## DETAILS OF COMPUTATION

The pressure-density data of Hyde,<sup>1</sup> Dow,<sup>2</sup> and Dow and Fenske<sup>3</sup> were plotted on graph paper of large enough scale that the coordinates of any point could be read to four significant figures. To facilitate computation, density ratios  $\rho/\rho_0$  were plotted against pressure.  $\rho$  is the density in g/cm<sup>3</sup> at any fixed temperature and pressure and  $\rho_0$  is the corresponding density at the same temperature and atmospheric pressure. Temperature is expressed in degrees Fahrenheit and pressure in pounds per square inch gage. Curves were constructed for temperatures of 77°, 104° and 167°F. They were found to have the same general shape as those obtained by Bridgman<sup>5</sup> for many pure liquids; i.e., the density increases quite rapidly as pressure is first applied but at a slower rate at higher pressures. For example, in the case of oils at 104°F the density increases by about 5.3 percent for the first 15,000 lb./in.2 but only by an additional 3.2 percent for the next 15,000 lb./in.<sup>2</sup>.

The distribution of points with reference to the curves is of importance in determining the relative precision of the data. The three studies gave density values for twenty oils at various temperatures and pressures. Four of the oils had been studied at all three temperatures, five at 104° only, and eleven at 104° and 167°F. It is evident that the data are not enough for a critical study of accuracy by the method of least squares. Consequently, curves were drawn in such a way that they passed through the averages of all the plotted points. At 77° the maximum

<sup>8</sup> P. W. Bridgman, Proc. Am. Acad. A & S 66, 185 (1931).

deviation of any point from the average  $w_{as\,0,1}$  percent; at 167°, 0.7 percent; and at 104°F, the most representative since data from all three studies were available, 0.9 percent.

Table I illustrates the distribution of the

densities measured at 10,650 lb./in.<sup>2</sup> for a temperature of 104°F. Three investigators, working with twenty different oils, are represented by the data. The arithmetic average is seen to be 1.03% as compared with 1.040 obtained graphically, indicating that the graphic method of averaging is sufficiently accurate. The average deviation from the mean of a single observation is seen to be  $\pm 0.002$  and the percentage deviation of the mean is  $\pm 0.04$ .

The absolute error involved in the measurements is probably somewhat greater than the precision might seem to indicate. Both the pistor displacement and the sylphon methods of measuring volume change are quite complicated in comparison with the simple and accurate method of weighing with a specific gravity bottle at atmospheric pressure. Furthermore, the measurement of the absolute pressure in the system introduces errors which are not involved in ordinary atmospheric gravity determinations Bridgman<sup>5</sup> indicates that the absolute error involved in the measurement of density under pressure might generally be expected to be 2 or 3

with at constant temperature. The fact that first is good agreement between the data of fide, who used the piston displacement method, withat of Dow, and Dow and Fenske, who used fit silphon method, would seem to indicate, surver, that the absolute error involved in the metaurements under consideration at constant entertature might be somewhat less than what end otherwise be expected.

Probably the source of greatest error lies in the arepolation and extrapolation. Data were availair at only three temperatures; namely, 77°, and 167°F. By interpolation and extrapolaet of these data, a system was evolved by of which densities can be calculated at arguals of 10° between the limits of 20° and TF. The method employed was to construct entive density-temperature isobars at atmosderic pressure, 10,000 lb./in.2, and 20,000 lb./in.2 merading off the relative densities at 77°, 104° ad 167°F from the relative density-pressure are already described. While only three points er used to determine these isobars, the uncerunty in locating the curves accurately was not a mat as might be expected at first thought. whitive density increases slowly with temperaat constant pressure, and for the experiintial range considered here does not depart mully from linearity. Moreover, the isobar at mospheric pressure could be located with exme accuracy with the aid of the National herau of Standards tables6 that show the change density of petroleum oils with temperature at anospheric pressure. At this point it is to be and that the National Bureau of Standards indicate that oils in the range of specific mity of the present ones under consideration un a thermal coefficient of expansion of \*X10<sup>-3</sup> per °F at atmospheric pressure. The mages of the corresponding values reported by and by Dow and Fenske<sup>3</sup> were  $37 \times 10^{-5}$ 11×10<sup>-5</sup>, respectively. This variation of the Scient can be taken as the possible error in r temperature measurements, since the appaused at the National Bureau of Standards a doubtless better suited to measuring the mespheric isobar than the sylphon apparatus

Autonal Bureau of Standards Circular C410, United Government Printing Office, Washington, D. C.

UUME 11, MAY, 1940

used by these other investigators. Thus the atmospheric isobar was first corrected to bring it into line with the National Bureau of Standards values, and the other isobars were then corrected correspondingly. By using this system of correction, the actual shape of the density-pressure curves was left unchanged, and the intercept on the density axis was corrected only to bring the atmospheric densities into line with the National Bureau of Standards tables.

## DENSITY EQUATION

In order to express the graphical results in a simple form that can be used readily for the calculation of density at various pressures and temperatures when the density at atmospheric pressure is known at a particular temperature, the following empirical equation was developed,

$$\rho = \rho_0 (1 + ap - bp^2)_{\iota}. \tag{1}$$

In this equation  $\rho$  is the density in g/cm<sup>3</sup> at any stated temperature *t* and pressure  $\rho$ , and  $\rho_0$  is the density at the same temperature at atmospheric pressure. Temperatures are expressed in degrees Fahrenheit and pressures in pounds per square inch gage. The symbols *a* and *b* represent constants at any given temperature. Values for *a* and *b* are given in Table II.

TABLE II. Density constants a and b as functions of temperature.

°F	a	b	Темр. °F	a	b
20	3.96×10-6	7.3×10-11	130	4.50×10-6	5.3×10 <sup>-11</sup>
30	4.02	7.0	140	4.53	5.1
40	4.08	6.8	150	4.56	5.0
50	4.14	6.6	160	4.59	4.9
60	4.19 、	6.4	170	4.61	4.8
70	4.24	6.2	180	4.63	4.7
80	4.29	6.0	190	4.64	4.6
90	4.34	5.8	200	4.66	4.5
100	4.38	5.7	210	4.67	4.4
110	4.42	5.5	220	4.68	4.4
120	4.46	5.4			

The method used to compute the values of a and b is readily explained. For each of the températures listed values of  $\rho/\rho_0$  were taken from the isobars constructed as described in a previous section, and a and b were evaluated using simultaneous equations of the type of Eq. (1). The values so calculated were then plotted as shown in Fig. 1 and Table II was constructed

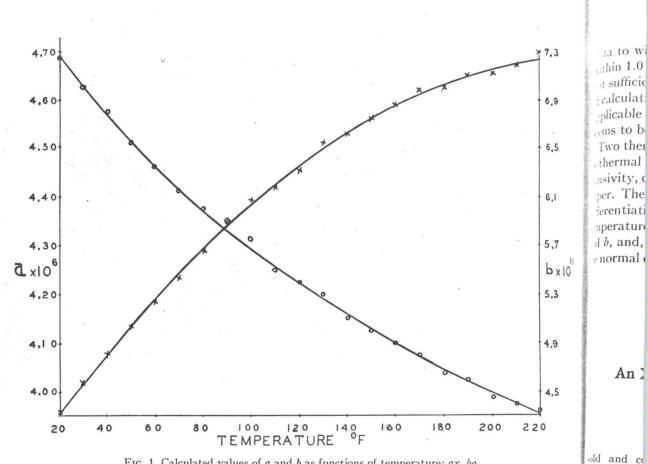

FIG. 1. Calculated values of a and b as functions of temperature; ax, bo.

from values read from smooth curves through these plots.

If the density of an oil is known at atmospheric pressure and it is desired to calculate its density at some other pressure, it is only necessary to refer to the values of a and b of Table II at the temperature under consideration and make the calculation by means of Eq. (1). If the known atmospheric density is at a temperature different from that required in the final answer, the atmospheric density is first adjusted to the desired temperature by means of one of the methods already known to the petroleum industry, as, for example, the National Bureau of Standards tables<sup>6</sup> referred to already.

## DISCUSSION

It is the belief of the writers that the system developed in this paper offers the best means so far described for the calculation of density of lubricating oils at various pressures from their

g deposited known densities at atmospheric pressure. to thermodynamic quantities of interest, the bernal compressibility and the thermal exwity, can be calculated from the data of this The compressibility can be obtained by miniation of the density equation at the occature corresponding to the constants a ), and, if computed at two pressures, shows mal decrease with increase of pressure. On

the other hand, if the compressibility is calculated at two temperatures, it will be found to increase with temperature. The thermal expansivity can be calculated by applying the density equation at two temperatures at constant pressure. If computations are made at two pressures it will be found that the expansivity decreases also with increase of pressure. In regard to these derived quantities it should be noted that they cannot be calculated to an accuracy claimed for the basic density data. However, this lack of accuracy becomes important only at the lowest pressures where possible inaccuracy in measuring pressure by means of the manganin coil is recognized.

## An X-Ray Method of Determining Rates of Diffusion in the Solid State

IME 11, MAY, 1940

action of diffusion alone, rapidly and automatically lose the higher Fourier harmonics of its periodic density distribution function and retain the fundamental in such a way as to render the determination of the diffusion coefficient quite accurate. The observed behavior of the diffracted maxima seem to support these expectations as does also the absence of any intensity in higher orders than the first. This purification by diffusion probably takes place principally during the depositing process itself while the temperatures are still quite high. Formulae are derived relating the observed rate of decay of the diffracted intensity, the artificial "grating constant" of the strata, and the diffusion coefficient. The method seems especially promising for substances and temperatures where diffusion is so slow as to be otherwise quite unobservable because the diffusion time varies as the square of the distance over which atoms must migrate and in this method these distances are many orders of magnitude smaller than in any other.

trolled evaporation in vacuum to produce artificially stratified layers of two different substances (gold and copper) was to develop, if possible, a technique of measuring the absolute wave-length of x-rays by a type of diffraction more nearly resembling Bragg reflection than is the case in the
