

Other derivatives gave different conversions; the 4,4'-DMBA showed an especially small yield. The amount of product formed varied also with the medium. In Figure 16 we exhibit a simple configuration coordinate diagram where the mode involved is the reaction coordinate. In the original paper

Figure 16. Configuration coordinate diagram for conversion between A and B forms

calculations using equation (1) demonstrate that the thermal process is directly from the A ground state to the B ground state to the B ground state; i.e. no thermal occupation of the excited A state is involved. In the steady state

$$(1 - x) \exp(-E_{c1}/kT) = x \exp(-E_{c2}/kT) \quad (2)$$

or

$$x = 1/[1 + \exp(E_D/kT)] \quad (3)$$

where x is the fraction converted and E_{c1} , E_{c2} and E_D are defined in Figure 16. A plot of E_D/kT vs pressure for BA is shown in Figure 17. If equilibrium has been reached, one can calculate the increase in yield upon raising the temperature, using E_D evaluated from room temperature data. As shown in

Figure 17. E_D/kT ($\Delta G_{AB}/kT$) against pressure: BA in PMMA

the original paper, equilibrium is indeed attained. One can then consider E_D as a free energy difference ΔG_{AB} , and write:

$$\partial \ln K / \partial p = -\partial \Delta G_{AB} / \partial p = -\Delta \bar{V}_{AB} / kT \quad (4)$$

where $\Delta \bar{V}_{AB}$ is the difference in partial molar volumes between the two states. Typical values appear in Table 2. The volume of the B state is less than that of the A state, but its compressibility is less also, so that at sufficiently high pressure they should attain the same volume. $\Delta \bar{V}_{AB}$ for 4,4'-DMB is noticeably smaller than that for the other derivatives. This is not surprising in view of its different conformation, but it is of interest to have a quantitative measure.

The difference in behaviour between BA in PMMA and in PS is illustrated in Figure 18, where E_D/kT ($\Delta G_{AB}/kT$) is plotted against ρ/ρ_0 . The plots

Figure 18. E_D/kT ($\Delta G_{AB}/kT$) against ρ/ρ_0 : BA in PMMA and in PS

appear linear although there is considerable scatter, and the range is short, so this point should not be overemphasized.

Qualitatively one associates the decrease in E_D with increasing density with a stronger attractive interaction of the B state with the medium than that for the A state. This could be associated with a larger dipole moment and/or polarizability for the A state. While either state apparently has a permanent dipole moment, the electronic states of the two forms apparently differ enough to allow quite different polarizabilities. It may be relevant
