Institut für Metallphysik der Universität Göttingen Hydrostatic Pressure and Plastic Deformation of the Alkali Halides By

G. FONTAINE¹⁾ and P. HAASEN

The effect of hydrostatic pressure on the plastic deformation of metal single rystals is not very important (1): a small rise in flow stress can be interpreted a terms of the work done against pressure to produce the volume increase associated with plastic deformation. This volume increase is due to anharmonic effects a the long range elastic field of dislocations, the core effects being negligible (2). On the other hand alkali halides show a marked dependence of flow stress on hydrostatic pressure (3, 4). The purpose of this note is to show that in ionic solids the presence of dislocations with dissociated cores on (110) planes (5) is compatible with the observed pressure effect.

In alkali halides the stacking fault energy y(x) for a $(x/\sqrt{2})$ [110] (110) fault is quite well approximated by (5)

$y(x) = y \sin^2(\pi x/b),$

where b is the absolute value of the perfect Burgers vector of the structure and J_0 the energy of a b/2 Burgers vector fault. Faulting introduces a strong dilatation t_0 the energy of a b/2 Burgers vector fault. Faulting introduces a strong dilatation t_0 between the two planes adjacent to the stacking fault. ε is a maximum for the b/2 fault being then equal to ε_0 ($\varepsilon = \delta d_{(1\bar{1}0)}/d_{(1\bar{1}0)}$ with $d_{(1\bar{1}0)} = b/2$). Taking into account electronic polarization of the ions in the neighbourhood of the fault, computed values are $\gamma_0 = 330 \text{ erg cm}^{-2}$, $\varepsilon_0 = 0.27$ for lithium fluoride, and $\gamma_0 = {}^{2}.95 \text{ erg cm}^{-2}$, $\varepsilon_0 = 0.32$ for sodium chloride. γ (x) has no minimum in the range 0 < x < b. Thus the stacking fault cannot extend all through the crystal on a (110) plane since it is not even a metastable defect. It is possible, however, to speak of a dislocations tabilizing the stacking fault. Since there is no local minimum in γ (x) one considers a continuous distribution of partial dislocations of a density ρ (x). In a more

quantitative approach we choose ϱ to be constant in the range $\neg d \leq x \leq d.$ Since for the total dislocation

$$\int b\varrho (x) dx = b$$

 $\varrho(x) = 1/2d$ for |x| < d, and 0 otherwise, the centre of the dislocation being at x = 0. At x the absolute value of the Burgers vector defining the stacking fault is equal to

$$b(x) = \int_{\frac{d}{d}}^{A} b\varrho(x) dx = b \frac{x+d}{2d}$$

for |x| < d and 0 otherwise.

Thus between x and (x + dx) we have a strip of stacking fault with the energy

$$\left[b(x)\right]dx = \gamma \cos^2(\pi x/2d) dx$$

for |x| < d.

The width d of this function defining the dissociation is obtained by minimizing the total energy with respect to d. This total energy consists of five contributions. 1. The energy of the stacking fault strips "'

 $\int \gamma[b(x)] dx = \gamma_0 d$

2. The interaction energy between partials which is about

$$= [\mu b^2/2\pi(1-\nu)] \int \int dx dx' \varrho(x)\varrho(x') \log(|x-x'|/b)$$

=
$$- [\mu b^2/2\pi(1-\nu)] (\log(2d/b) - 3/2),$$

where µ is the shear modulus and y the Poisson ratio.

3. The interaction energy between "Frank partials" due to the dilatation ε perpendicular to the fault. To get a rough estimate of this energy we assume that ε varies linearly from 0 for x = +d to ε_0 for x = 0. The interaction energy betwees Frank partials of the continuous distribution so introduced is then equal to

$$- \left[\mu \epsilon_0^2 b^2 / 8\pi (1 - \nu)\right] (\log(d/4\pi) - 3/2).$$

Short Notes

the self-energy of the partials is $\mu b^2/2 \int \frac{\rho}{\rho} (x) dx = \mu b^2/2$ for the first subution and $\mu c_{\lambda}^2 b^2/4$ for the Frank partial distribution.

The work done against the external hydrostatic pressure p to produce the mation ε . With the linear approximation for ε in 3., this term is simply equal $\varepsilon_{\rm b}$ bpd/2.

Minimizing the sum of the preceding five contributions with respect to d we ain the dissociation width

$$d = \frac{\mu b^{2} (1 + \varepsilon_{o}^{2}/4)}{2\pi (1 - \nu)(\gamma_{o} + \varepsilon_{o} bp/2)} .$$

p = 0 typical values of d/b are 8 and 6 for LiF and NaCl, respectively. It is an from the last equation that a hydrostatic pressure p must have some effect an \mathcal{E}_0 bp/2 becomes comparable to γ_0 . To obtain an order of magnitude we me a critical pressure p_0 such that

$$\epsilon_{\rm bp}/2 = \gamma /10$$
.

Les of p_c are 6 kbar for LiF and 4 kbar for NaCl. Experimentally (3) no presreflects are found for LiF at 4.3 kbar. At the same pressure effects are, howre, detected for NaCl, and also for LiF tested at 13 kbar (3, 4) (observed is an rease in the flow stress and a decrease in dislocation mobility). Of course the mement found here with our calculation must be considered to be only semimultitative because of the arbitrary definition of p_c . At least it explains the obred difference between LiF and NaCl. On the other hand, the action of p results her arrower dissociated core, thus easier cross-slip which is difficult to associate 2 the observed increase in flow stress.

Finally such pressure effects can be expected in all cases where a dilatation its at stacking faults. For example in b.c.c. metals the 1/8 [110] (110) fault duces a compression of the planes adjacent to the fault. These become closer /39 as seen from hard spheres considerations (6). Thus hydrostatic pressure help dissociation markedly for $p \ge p_c$. With $bp_c/39 \approx \gamma_o/10$ and with $\gamma_o =$ 135 µb for iron (6), $p_c \approx 42$ kbar. As far as we know, experiments on iron de crystals under such high hydrostatic pressures have not yet been reported.

Deutschen Akademie der Wissenschaften zu Berlin (b) w-Induced Electron Paramagnetic Resonance of ²S_{1/2}-State Impurity Centres in CdS and CdSe Single Crystals

By

R. BÖTTCHER (a) and J. DZIESIATY (b)

Recently ${}^{2}S_{1/2}$ -state impurities with $(ns)^{1}$ -configuration have become an intergobject of EPR investigations in II-VI compounds. Räuber and Schneider (1, aved spectra of Group-III elements, Sugibuchi and Mita (2, 3) the spectra of φ -IV elements in ZnS, and Suto and Aoki (4, 5) found spectra of Pb-associated res in ZnTe. From the extremely large hyperfine splitting by the nuclear spins me isotopes of the impurity centres, Räuber and Schneider, and also Sugibuchi Lita concluded that the unpaired spin is strongly localized in the (ns)-orbital φ impurity ion. In contrast to the observations in ZnS, the investigations in hPb and ZnTe;Ge (6) show large g-shifts to values greater than the free-spin φ and an additional superhyperfine structure, caused by the interaction with $\frac{3}{2}$. Suto and Aoki (7), and Iida and Watanabe, who calculated the probability φ the unpaired spin in the (ns)-orbital of only 0.23 for Ge and 0.19 for Pb (8), φ invound the Ge or Pb ion.

¹⁹ get further information about the nature of these centres we extended the ¹⁴ rements to single crystals of CdS and CdSe with wurtzite structure. ¹⁵ EPR measurements were performed with an X-band rf-modulated JEOL-¹⁶ Tometer JES-3BQ. The samples were prepared by two methods. Either by ¹⁶ ling single crystals of CdS and CdSe with the doping material or by growing ¹⁶ crystals from highly purified CdS and CdSe powder with an admixture of the ¹⁶ material. In both cases strong EPR-spectra were observed at 77 ⁰K after ¹⁶ taition with light in the visible range from an ordinary prism monochromator
