

a different objective, involved the reaction of a manganese-nickel mixture of approximately 12:1 ratio by weight, respectively, with carbon. The plan of the test was to maintain the temperature at the relatively high value necessary for diamond formation through reaction of manganese and carbon (approximately 1500° C. Fig. 10), whereupon the manganese would be progressively removed from the solvent alloy by carbide formation (approssimately 1000° C.). The effects looked for were both an overall rate of proximate solubility and transfer rate of carbon to the manganese-rich reaction. Diamond formation from the temperature maintained was excessive for diamond formation from the temperature maintained was observed by use of this technique. The only crystallinity "reduced" Mn-Ni solvent, diamond growth was realized essentially from a simple Mn-C reaction. Crystals both of high purity and quality from a well performed experiment have been obtained by use of this technique. The only inclusions observed were subject to reasonably rapid growth mechanism. It has been observed generally that both the rate of growth and crystal size were subject to reasonable temperature control. For example, as previously mentioned, higher temperature (within proper P-T bounds) usually yielded a greater number of crystals but of smaller size. The situation is reversed at lower temperatures, primarily due to a lesser number of nucleation sites. In addition, crystallization, normally initially prolific, is observed to diminish rapidly. The total yield from three minute experiments is not remarkable different from a nine minute experiment. New crystal formation is not rapid under steady state conditions, one. Following initial precipitation and crystallization, a system rapidly achieves equilibrium. Although new diamond formation essentially ceases of existing crystals. The more perfect is the coalescence. Coalescent growth longer the time, the more perfect is the coalescence.

Raising the temperature, supersaturation can be re-established with subsequent spontaneous precipitation. By cycling, within proper pressure-solvent limits for a given system, new growth can be rhythmically raised the temperature, precipitation can be re-initiated. By lowering the temperature, precipitation can be terminated. By also is a commonly observed phenomenon with the highly covariant metal, SIC. This is a cross sectioned specimen showing a nickel-chromium-carbon reaction carried out at high pressure and temperature. The needle-like phase in the metallic area is Cr<sub>3</sub>C. The mottled gray-black area at top center is unreacted graphite.

An experiment performed utilizing a somewhat similar combination of solvents, namely a carbide former and non-carbide former, but directed to Ni-Cu-C.

Metallic solvents also may be achieved by the use of lower melting neutral elements such as copper; for example, systems such as Al-In-Cu-C, or
